## Abstract

The energy dissipation and femtosecond dynamics due to fast heavy ions in matter is critically reviewed with emphasis on possible mechanisms that lead to material modifications. Starting from a discussion of the initial electronic energy-deposition processes, three basic mechanisms for the conversion of electronic into atomic energy are investigated by means of Auger-electron spectroscopy. Results for amorphous Si, amorphous C and polypropylene are presented and discussed. Experimental evidence for a highly charged track region as well as for hot electrons inside tracks is shown. As follows mainly from Auger-electron spectroscopy, there are strong indications for different track-production mechanisms in different materials.

## 1. Introduction

A fast heavy ion may lead to permanent material changes in a small volume surrounding the virtually straight ion path. The high electronic energy deposition gives rise to the formation of a chemical or structural defect cluster of cylindrical shape with an extremely large aspect ratio exceeding 1:1000. Such a defect cluster and its electronic and atomic precursors are denoted as ion tracks. The appearance of track effects in polymers is known since some decades [1] and has found widespread applications in the meantime [2]. Nowadays it is known that other insulators and even metallic glasses [3] are also subject to material modifications by heavy

ions. There are, however, a few seemingly contradictory models for the track-production mechanisms and until now most of them cannot completely be ruled out. In order to reveal the present status and the weak points of our present knowledge, a review of the possible scenarios of the track evolution is given. Special emphasis is devoted to the short-time phenomena from the initial excitation and ion-energy loss processes to the electronic deexcitation processes.

Fig. 1 displays a schematic view of the time dependence of the ion-track evolution. The upper part shows the rapidly passing projectile (dashed arrow). Once the projectile has reached its equilibrium

Fig. 1. Time evolution of an ion track. The initial excitation and ionization of atoms induces atomic motions, which freeze out and may lead to permanent rearrangements. In the bulk this may lead to structural or chemical modifications. At the surface craters or blisters on an atomic scale can be produced.

charge state, there will be only minor fluctuations of its internal state and it will move with constant velocity along a straight-line trajectory until deep inside the solid. Thus, the projectile ion acts as a well defined and virtually instantaneous source of strongly localized electronic excitation. According to Bethe's equipartition rule, about 50% of the total electronic energy is deposited inside the so-called infra-track radius of about 1 nm around the projectile path at projectile energies of a few MeV per nucleon. Excitation times are $10^{-19}$ to $10^{-17}$ s for inner-shell processes and reach $10^{-16}$ s for collective electronic excitations (plasmon production).

After these initial ionization and excitation events, the electronic system evolves further. The most important parameters that drive subsequent the solid-state evolution are the *local electron-energy density* and the *local ionization density*, as will be explained below. Most experimental techniques do not have direct access to these quantities. The closely related *total ion-energy loss* and the degree of *inner-shell ionization*, however, are subject of many investigations and they are discussed in Sections 2 and 4 for the case of fast heavy ions.

After the initial energy-transfer by heavy ions, electrons have escaped and the center of the track is highly ionized. Depending on the ionization density and on the *charge-neutralization time*, the mutual repulsion of positively charged target ions may convert a significant amount of the stored electronic potential energy into atomic motion. This conversion mechanism is described by the *Coulomb-explosion model* [1,4–6] and the corresponding electrostatic potential is discussed in Section 5. Coulomb explosion will be significant only if the charge-neutralization time exceeds $10^{-14}$ s for light target atoms and $10^{-13}$ s for heavy atoms.

Perturbation theory predicts neutralization times of about $10^{-16}$ s (given by the inverse plasmon frequency) for a weak and homogeneous charge displacement in free-electron gas-like metals, such as Al. Thus, for most metals charge neutralization might be fast and Coulomb explosion is impossible. Nevertheless, one has to consider that there is an extremely high charge density at the center of heavy-ion tracks. Furthermore, the spatial density of excited plasmons might already be saturated due to the passage of the ion. For highly charged ions such

3

effects go beyond perturbation theory and might have a severe influence on the collective electron properties. Thus, an experimental determination of charge-neutralization times is needed in order to judge about the importance of the Coulomb-explosion mechanism.

Even if charge-neutralization is rapid, electronic recombination might still be slow, leading to a hot electron gas at the center of the track. Two different mechanisms may then convert this internal electronic energy (quantified by an *electron temperature*, as discussed in Section 6) into atomic motion.

- The *lattice-relaxation model* [7,8] describes a collective atomic rearrangement due to (predominantly repulsive or antibinding) non-equilibrium interatomic potentials. Thus, a fraction of the electronic potential energy, or equivalently the degree of target excitation, leads to *modified interatomic forces* and subsequent atomic motion in this model.
- The *electronic thermal-spike model* [9–14] assumes that electronic excitation leads to the formation of a hot plasma and, via the electron–phonon coupling (equivalent to electron–atom collisions), to an increased thermal atomic motion. Thus, except for the efficiency of the *electron–phonon coupling*, the mean kinetic electron energy is the main ingredient in this model.

The relative importance of the three mechanisms depends on the charge-neutralization time, on the strength of the modified interatomic forces and on the electron–phonon coupling constant. For highly excited ion tracks, all of these quantities are uncertain or even unknown and, thus, the influence of a certain mechanism can only be determined experimentally. This, however, is complicated by the fact that atomic motion in solid matter may be converted into a stochastic motion on a time scale of $10^{-13}$–$10^{-12}$ s, largely independent of the early stage of the evolution. This situation is depicted in the center part of Fig. 1. Furthermore, slow atomic relaxation processes, such as recrystallization, and the influence of local structures and delay times on phase transitions may prohibit any definite conclusions. Hence, there seems to be no way to distinguish between the models on a pure experimental

basis, if only the resulting modified material properties such as in the lower part of Fig. 1 are investigated.

One possible way to improve the interpretation of material modification effects is the investigation of prompt emitted 'particles' that carry information from inside the track. Ejected electrons or X-rays can be used as precursors of the corresponding transient material states. Electrons may be probes for the first $10^{-18}$–$10^{-14}$ s of the track formation and energy dissipation. For reviews on transport of fast electrons and fast-ion-induced electron emission from solids, the reader is referred to [15–18].

## 2. Initial interaction processes, charge states and ion-energy loss

In this section, the initial interaction processes and projectile-related quantities will be discussed. Regarding the state of the projectile, inelastic collision processes depend on

- the projectile-nuclear charge $Z_p$;
- the projectile-charge state $q_p$ and only to a minor extend on the degree of internal projectile excitation inside the solid;
- the dynamic projectile screening (dressed projectile potential) due to the polarization of target valence- or conduction-band electrons as well as inner-shell electrons;
- the projectile velocity $v_p$. Throughout this paper, $v_p$ will be given in units of the Bohr velocity $v_B$ of $2.19 \times 10^6$ m/s corresponding to 25 keV/u or equivalently 1 a.u. (atomic unit).

### 2.1. Solid- versus gas-phase excitations

In solids there is no open experimental access to most dynamic quantities regarding the projectile as well as the target. Hence, it seems appropriate to discuss the corresponding processes for individual ion–atom collisions, where the cross-sections for all single-electron transitions are reasonably well known and understood. Before we look closer at these cross-sections, however, we should first consider the differences between thin gas targets at

4                    *G. Schiwietz et al. / Nucl. Instr. and Meth. in Phys. Res. B xxx (2004) xxx–xxx*

187 moderate pressures and solid-state targets at typical
188 densities. At room temperature for a gas pressure of
189 1 atm the atomic gas density is by three orders of
190 magnitude lower than the corresponding solid-state
191 density. Exactly this difference in the mean inter-
192 atomic distances is solely responsible for all solid/
193 gas differences of electronic excitation processes. It
194 leads to the following effects:

195 1. Inside solids the *collision frequency* is enhanced
196    by 6 orders of magnitude in comparison to a
197    gas target at typical gas-cell pressures. Beyond
198    the pure statistical enhancement of transition
199    rates, this leads to the ionization of excited states
200    that are populated in a previous collision. Thus,
201    electrons in excited states are stripped off before
202    they may decay to the ground state inside solids.
203    In gas targets such highly excited projectile states
204    decay preferentially via an X-ray transition
205    before the next collision takes place, thereby sta-
206    bilizing the lower projectile-charge state. Espe-
207    cially for fast heavy ions this difference results
208    in significantly increased projectile charges and
209    stopping forces in solids [19–22].
210 2. Inside solids the *level structure* is modified due to
211    the presence of neighboring atoms. For inner
212    shells the relative effect is small, but for valence
213    bands there is a considerable influence of elec-
214    tron hopping and the energy gaps may vanish.
215    The influence of the gap on the energy loss is
216    important only at low velocities, where mainly
217    valence electrons are involved [23].
218 3. Inside solids *collective excitations* (*plasmons*)
219    appear as a new energy-loss mechanism. For fast
220    projectiles, however, this excitation mode sup-
221    presses the dipole-type atomic excitation proc-
222    esses via the plasmon screening (wake
223    potential) discussed below. Thus, for fast ions
224    the total energy loss as well as its impact-param-
225    eter dependence are barely influenced by the
226    plasmon screening.
227 4. Inside solids there is a *dynamic projectile screen-*
228    *ing* due to electrons of the valence and conduc-
229    tion bands that are attracted by the positively
230    charged projectile. This collective effect reduces
231    the strength of the projectile/electron interaction.
232    At low velocities it is described by the Thomas–
233    Fermi screening-length and at high velocities it

234 results in the so-called wake potential related to
235 plasmon excitation [24]. As mentioned above,
236 there is a cancellation of effects for swift parti-
237 cles. Thus, the screening effect becomes impor-
238 tant only at low velocities [25], where plasmon
239 excitation is suppressed.

240
241 Summarizing the above remarks, two marked
242 differences between the energy losses in solids and
243 individual atoms may be noted. Slow light ions in-
244 volve reduced energy losses due to the long-ranged
245 solid-state screening (see item 4 above). More
246 important for the subject of this review, however,
247 is the behavior of swift heavy ions. For these ions,
248 the energy loss in solid is enhanced due to increased
249 charge states (see item 1 above). Thus, atomic cross-
250 sections should yield a reliable picture of the direct
251 ion–solid interaction processes for fast heavy ions
252 as long as we consider the differences in the
253 charge-state distributions.

254 *2.2. Velocity dependence of electronic processes*

255 Fig. 2 displays schematic cross-sections for all
256 basic single-electron reactions in ion–atom colli-
257 sions. Actual numbers for these total cross-sections
258 have been taken from different sources for protons
259 on atomic hydrogen and also on helium. The scaled
260 velocity $v_p/v_o$ corresponds to a certain selected tar-
261 get-electron shell with the mean orbital velocity
262 $v_o$. For conduction-band electrons $v_o$ may be re-
263 placed by $2/3v_F$, where $v_F$ is the Fermi velocity.
264 The cross-section values are given in arbitrary units,
265 since there is no simple scaling that covers the full
266 range of small ($v_p/v_o \ll 1$) as well as large ($v_p/$
267 $v_o \gg 1$) velocities. Note that the displayed depend-
268 encies are typical for a fixed projectile-charge state.
269 The partial stopping cross-sections have shown in
270 the upper part of the plot are derived from the total
271 cross-section by multiplication with the average en-
272 ergy related to the different processes.
273 One may see that the excitation and ionization
274 cross-sections in Fig. 2 behave quite similar. They
275 are rising from low energies towards higher ones
276 until a maximum around $v_p = v_o$ is reached. At
277 higher velocities these cross-sections drop with
278 velocity and asymptotically they are proportional
279 to $Z_p^2 \ln(v_p^2)/v_p^2$ [26]. The cross-section reduction at

5

Fig. 2. Typical behavior of basic single-electron processes as a function of the reduced projectile velocity $v_p/v_o$ for a fixed projectile-charge state. The velocity-scaling parameter $v_o$ is the mean orbital velocity for a specific inner-shell or valence-band electron. The energy dependence for excitation, ionization and electron capture cross-sections are shown in the lower plot. The corresponding stopping cross-sections are shown in the upper plot, together with the so-called nuclear energy loss due to quasi-elastic projectile scattering.

high velocities is mainly due to the reduced interaction time. In other words, the probability for hitting a target electron is significantly reduced at high projectile energies. At intermediate energies ions slow down due to a manifold of different processes, all of similar importance. There are high transition probabilities at small impact parameters and even multi-electron transitions may dominate the collision process [27].

At low velocities the excitation and ionization cross-sections drop, since the target electron may adjust adiabatically to the projectile motion. A transient quasi-molecular orbital is formed and when both collision partners separate there is a high probability for the electron to return back to its ground state. For specific orbitals, however, quasi-molecular promotion and rotational coupling may

still lead to exceptional high transition probabilities. In this energy range the collision dynamics depends significantly on the projectile-charge state, impact parameter and on the specific projectile–target combination [28].

The capture cross-section is indicated by the hatched area on the left-hand side in Fig. 2. It falls drastically with increasing energy, since electron capture requires that a slow target electron adjusts to the high projectile speed (jumping onto a moving train). This is possible only at small impact parameters, where the electron velocity may exceed the mean orbital velocity. Asymptotically the electron-transfer cross-section is proportional to $q_p^5/v_p^{11}$ and leads to a peak structure in the projectile-angle distribution as predicted by second-order perturbation theory [29,30].

At low ion speeds electron capture is very sensitive to the details of the level structure of both collision partners. The upper and lower boundaries of the hatched area in the graph are representative for protons interacting with atomic hydrogen and with helium atoms, respectively. In the first case (H$^+$ + H) an electron may be transferred in a resonant process, keeping the binding energy unchanged. Thus, tunneling slightly below the potential barrier between projectile and target is the dominant reaction process. The second case (H$^+$ + He) requires an energy transfer that is very unlikely, especially at large impact parameters. This leads to orders-of-magnitude reductions for the non-resonant electron-capture probabilities. At low projectile energies target as well as projectile excitation and ionization are also significantly dependent on the details of the collision system and especially for outer-shell processes no simple scaling rules apply. The corresponding cross-section variations are typically less pronounced than for the capture process. For the sake of simplicity these variations are not shown in the figure.

So far we have considered only an individual target-electron shell in the above discussion. Let us now turn to the more global behavior. At high energies, where the projectile is much faster than even the target K-shell electrons, all electrons contribute very similar to the projectile energy loss. The excitation and ionization cross-sections are significantly reduced for deeply bound target shells, but the

mean energy transfers are enhanced in an approximately reciprocal manner. Thus, the binding energy is of minor importance for electrons below a certain threshold-binding energy. At high energies the effect due to all shells may be summarized by a shell-averaged mean target-excitation energy as it appears in the Bethe logarithm of Bethe's famous stopping-power formula [31,32]. Using such an averaged energy, the corresponding averaged orbital velocity would scale with the square root of the target nuclear charge $Z_t$. At intermediate projectile velocities, however, inner shells do not contribute to the energy loss. Thus, a much weaker $Z_t$ dependence of the averaged velocity is expected close to the stopping-power maximum. One may estimate that the stopping-power maximum in Fig. 2 varies only between about 50 and 300 keV/u for solid-state targets of the whole periodic table, but restricted to light ions. For proton beams this estimated energy range matches the experimental results to within a factor of 2.

As indicated in the discussion further above, however, the variation of the projectile-charge state is very important and has to be considered for projectiles with higher nuclear charges. The hatched rectangle on the right-hand side of the figure corresponds roughly to the experimental stopping-power maxima for heavy ions if we consider the shell-averaged velocity scaling parameter for the x-axis. This seems to be in contradiction with the plotted partial stopping-power curves (with their maximum close to $v_p = v_o$), but one has to keep in mind that the projectile-charge state variation with velocity is not included in these curves. Nevertheless, for the velocity regime where ion tracks are produced (hatched rectangle) one may summarize as follows. Electron capture and projectile-electron loss are important only insofar as they determine the projectile-charge state. Target ionization processes, often with high energy transfers, clearly dominate the shell-averaged stopping force.

For few-electron systems (H + H or H + He), there exist accurate quantum-mechanical solutions of the time-dependent Schrödinger equation, yielding stopping powers that agree to within a few percent with the experimental data. The remaining discrepancies may even be traced back to result from the neglect of electron-correlation effects

[33,34]. Also impact-parameter dependent ionization probabilities and electronic energy transfers are in reasonable agreement with available experimental data [35]. The situation is less satisfying for many-electron systems as they are typical for ion–solid interactions. However, the whole treatment simplifies again if we restrict ourselves to fast projectiles. As shown above, fast ions loose their kinetic energy mainly through ionization of atoms from all shells and to some extent through excitation of valence- and conduction-band states. Although the current experimental uncertainties of energy-loss determinations are much below the theoretical uncertainties, these energy-loss mechanisms are expected to be qualitatively well understood.

Different attempts for a precise description of the energy loss of swift ions in multi-electron targets are currently being worked out in the frame work of simplified models [36–40]. They rely on an explicit consideration of the different projectile-charge states and the corresponding projectile screening due to bound electrons. Furthermore, they include projectile excitation and ionization processes as well as higher order terms that go beyond perturbation theory. Especially for heavy ions, accurate equilibrium charge-states are needed if the energy-loss prediction should reach a precision below 10%. For heavy ions at 5 MeV/u such charge-state data are presented and discussed in the next paragraphs.

### 2.3. Non-equilibrium and equilibrium charge states

Fig. 3 displays experimental as well as theoretical mean projectile-charge states $\overline{q}$ for different carbon foils of thicknesses between 4 and 50 μg/cm². The experiments have been performed with a stripper foil in a focal point a few m downstream of the ISL heavy-ion cyclotron [41]. The charge-state distributions have been measured by using a dipole magnet coupled with a quadrupole triplet to focus each selected final charge-state fraction of the beam into a widely open Faraday cup. The resulting uncertainties are typically below 0.2 charge units for a stable beam and a homogeneous stripper foil. The initial charge states are indicated as arrows on the left axis.

The projectile-charge state is determined by the balance of electron capture and projectile-electron
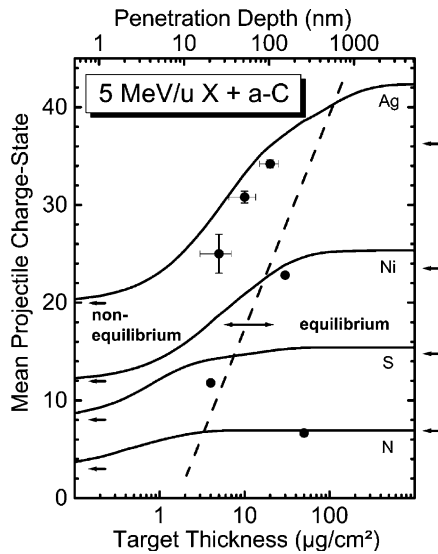

Fig. 3. Measured mean projectile-charge states $\bar{q}$ for different ion species as a function of the target thickness in comparison with theoretical predictions [42]. The arrows on the left-hand side indicate the initial charge states. The arrows on the right-hand side of the frame indicate the mean equilibrium charge-states as determined from an accurate fit to a nearly complete set of published data.

439 loss as well as by the excitation, Auger and optical
440 decay of excited projectile states. A few single-elec-
441 tron models exist for the solution of the rate equa-
442 tions that govern the evolution of the projectile-
443 state population. Only one code, however, is known
444 to us that allows to treat projectiles with up to
445 about 9 bound electrons [42]. Explicit consideration
446 of all sublevels of the K, L and M shells and all pos-
447 sible populations for all charge states would require
448 to solve an unfeasible amount of coupled rate equa-
449 tions with the corresponding transition rates. Using
450 reasonable assumptions, this system of equations is
451 reduced to only 81 coupled equations, which are
452 solved numerically. Results of this model are de-
453 picted as solid curves in Fig. 3.
454     Fitted equilibrium charge states $\bar{q}$ for the limit of
455 large target thicknesses are indicated as arrows on
456 the right side of plot. These precision charge-states
457 fits are discussed further below.
458     The solid curves show a monotonously increas-
459 ing mean charge state with increasing target thick-
460 ness. These curves overestimate the experimental

461 data and the equilibrium-fit results by up to 6
462 charge units for the heaviest projectile ion. These
463 deviations can be related to uncertainties of the cal-
464 culated transition cross-sections. They point to
465 underestimated capture cross-sections (neglect of
466 capture into highly excited states) and to overesti-
467 mated electron-loss cross-sections (typical for per-
468 turbation theory). The theoretical curves as well
469 as the experimental data for Ag show the impor-
470 tance of non-equilibrium charge-states, which are
471 directly related to non-equilibrium energy losses in
472 thin-film experiments. For heavy ions at a few
473 MeV/u stopping powers might be strongly reduced
474 (roughly proportional $q^2$) in the first few hundred
475 nm. An approximate boarder line between non-
476 equilibrium and equilibrium thickness at 5 MeV/u
477 is indicated by the broken line in Fig. 3. Before
478 we turn to a specific property of heavy ion stopping
479 at equilibrium, however, we should discuss equilib-
480 rium charge states in somewhat more detail.
481     Qualitatively the mean projectile-charge state is
482 given by the Bohr stripping criteria which states
483 that all projectile electrons with orbital velocities
484 below the projectile velocity are stripped off. This
485 means at equilibrium we have $v_p/v_o \lesssim 1$ for the out-
486 ermost bound projectile electron. In fact, for pro-
487 tons in hydrogen there is a crossing of the cross-
488 sections for resonant capture and ionization (simi-
489 lar to the crossing in the lower graph of Fig. 2) at
490 $v_p/v_o \approx 1.4$. Thus, the mean charge state is 0.5 at this
491 velocity, since the electron capture and loss rates are
492 about equal.
493     For highly charged heavy projectiles the elec-
494 tron-loss cross-sections decrease with the outer-shell
495 binding-energy and, hence, with the projectile
496 charge. The maximum capture cross-sections on
497 the other hand increase significantly with the pro-
498 jectile charge, but compared to Fig. 2 there is a stee-
499 per velocity dependence at high energies. This
500 charge-state dependent behavior of the capture
501 cross-section stabilizes the critical velocity ratio
502 $v_p/v_o$ where capture and loss involve equal cross-sec-
503 tions. Typical critical ratios are $0.9 < v_p/v_o < 1.7$.
504     From this discussion it is obvious that the Bohr
505 stripping criteria should not be taken too serious.
506 Furthermore, as discussed above, it would require
507 enormous theoretical efforts to handle projectiles
508 carrying many electrons in an ab initio treatment.

*G. Schiwietz et al. / Nucl. Instr. and Meth. in Phys. Res. B xxx (2004) xxx–xxx*

509 Therefore accurate charge-state predictions for fast
510 heavy projectiles do still rely on semiempirical fits to
511 experimental data. The results of an advanced
512 charge-state fit are described in the following.
513     Fig. 4 displays experimental data for the reduced
514 projectile charge $\overline{q}/Z_p$ as a function of a general
515 velocity scaling-parameter $x$. Bohr has proposed a
516 velocity scaling-parameter $x = Z_p^{-2/3}v_p/v_B$ [43]. We
517 have checked that the use of this scaling leads to
518 average uncertainties of 1.7 charge units ($\pm5.1\%$)
519 in comparison to the available experimental data.
520 Stopping powers derived from the Bohr scaling
521 would be uncertain by $\pm10\%$, even if an otherwise
522 perfect energy-loss theory is used. Thus, we have
523 decided to search for a more accurate scaling of
524 the mean charge states. A multi-parameter least-
525 square fit [21] has been applied to published solid-
526 state data for about 840 experimental data points.
527 Protons and helium ions above a velocity of $v_p/$
528 $v_B = 2$ and all heavier ions above $v_p/v_B = 0.4$ have
529 been considered. For slower projectiles we find sig-
530 nificant deviations from simple scaling properties
531 and band-structure effects seem to be of impor-
532 tance. Here we present charge-state formulas with
533 asymptotic dependencies that are improved with re-

spect to previous results [21]. Furthermore, reso- 534
nance effects and in addition also shell-structure 535
effects have been considered in an iterative fitting 536
procedure, resulting in 537

$$\overline{q} = \frac{Z_p(8.29x + x^4)}{0.06/x + 4 + 7.4x + x^4}, \qquad (1)$$

with the scaling variable $x$ 541

$$x = c_1(\tilde{v}/c_2/1.54)^{1+1.83/Z_p}, \qquad (2)$$

the two correction terms 545

$$c_1 = 1 - 0.26\,e^{-Z_t/11}\,e^{-\frac{(Z_t-Z_p)^2}{9}}, \qquad (3)$$

$$c_2 = 1 + 0.030\tilde{v}\ln(Z_t), \qquad (4)$$

and with the scaled projectile velocity 552

$$\tilde{v} = Z_p^{-0.543}v_p/v_B. \qquad (5)$$

The four numerical parameters in Eq. (1) where 556
determined at each step of the optimization by an 557
automatically weighted least-square fit that mini- 558
mizes the absolute charge-state deviation. The 559
remaining seven parameters in Eqs. (2)–(5) are to 560
a large extend independent of each other and where 561

Fig. 4. Measured mean equilibrium projectile-charge states $\overline{q}$ divided by the corresponding projectile-nuclear charges $Z_p$ for all ion species and all solid-state targets as a function of the scaling variable $x$ (see text). $Z_p$ is color-coded allowing to separate the different data sets. The solid curve is an accurate fit to this nearly complete set of published charge-state data.

9

varied manually. The power term in Eq. (2) serves to adjust the steepness of the charge-state curves as a function of $x$. It modifies the scaling behavior at small projectile-nuclear charges. The correction term $c_1$ accounts for resonant electron capture which reduces the mean charge state $\bar{q}$ or equivalently $x$ for symmetrical projectile–target combinations. The correction $c_2$ accounts for a target dependent deformation of the charge-state curves at high velocities.

The main deviation of our fit result from the Bohr scaling is the exponent $-0.543$ in Eq. (5). Due to the $Z_p$ dependence in Eq. (2) the exponent is effectively reduced to about $-0.46$ in the vicinity of $x = 0.5$. This exponent is very close to $-0.45$ found by Nikolaev and Dmitriev [44] for heavy ions, but far from $-2/3$ predicted by Bohr [43].

A mean squared deviation of about 0.37 charge units is reached with formulas (1)–(5). With consideration of shell-structure effects, similar as shown in [21], the mean squared deviation from the experimental data is reduced to 0.28 charge units. Note that our ab initio stopping-power code CASP is now based on the above formulas and yields also charge states for arbitrary projectile/target combinations including target dependent shell effects [36,37]. Already our previous charge-state results [21] (less certain by roughly a factor of 2) have been shown to yield accurate stopping powers for MeV/u ions in carbon [40]. An analysis of 29 overlapping data points measured in different experiments with carbon targets shows that the pure experimental uncertainty is already 0.21 charge units. Considering this experimental error, we expect the absolute accuracy of the current fit to be about 0.2 charge units. Thus, it is hardly possible to improve the above fit without applying experimental reliability factors. Stopping powers derived from the current scaling include an error of only about ±2% due to the charge-state uncertainty.

## 2.4. Electronic energy-loss maximum

Let us now discuss electronic stopping forces in the region of high electronic energy depositions, as they are most important for track production. Here we will concentrate only on the question at which projectile energy one may expect the stopping-power maximum for a specific type of ion. This energy is, e.g., important if one tries to distinguish between material modifications processes due to either electronic ($S_e$) or the quasi-elastic nuclear ($S_n$) energy losses. Often measurements are performed for projectile energies corresponding to a fixed electronic energy loss on both sides of the stopping-power maximum.

Fig. 5 displays energy-loss cross-sections for He, Si and Au ions in C, Si and Au targets under equilibrium conditions. These projectile/target combinations cover a large fraction of the periodic table. The energy loss values stem from fits to experimental data and are obtained using the SRIM2003 code [45]. The ordinate in Fig. 5 is scaled just for convenience, in order to reduce the order-of-magnitude variations of the stopping-power values.

A particularly simple scaling was used for the $x$-axis in Fig. 5. Here the kinetic energy per nucleon is divided by the projectile-nuclear charge $Z_p$. It is seen that the stopping-power maxima of the different collision systems coincide approximately. The

Fig. 5. Scaled electronic energy loss for a few collision systems scattered among the periodic table as a function of a scaled projectile energy. Fit results for the electronic energy loss $S_e$ are used representative for the experimental data [45].

mean energy positions for the chosen projectile/target combinations correspond to about $E_p/M_p = Z_p \cdot 80\,\text{keV/u}$ and the variation around this value is about ±50%. Although this relation looks very simple, the explanation of this behavior is not trivial as will be discussed in the following.

Let us first concentrate on the target dependence of the stopping-power maximum for incident protons. Typical atomic outer-shell binding energies of metal atoms vary from 4 to 11 eV. The largest binding energies are found in the first two rows of the periodic table (H to Ne). Up to $Z_t = 4$ the outer shells are energetically clearly separated from the inner shells and the proton induced stopping-power maximum is determined by the valence band only. For heavier targets the situation changes and the large number of electrons in bands energetically somewhat below the valence band has a significant influence. Thus, the averaged binding energy for heavy targets is enhanced. Furthermore, the mean electron velocity in the valence band of heavy targets is somewhat larger compared to light targets due to the acceleration in the vicinity of the screened target nuclei.

Both effects, binding-energy blending and valence-electron acceleration, are similarly important as the valence binding-energies and lead on the average to increased energies of the stopping maximum for heavy targets. With these arguments it becomes also clear why Li has a very low stopping-power maximum at about 40 keV. This metal has slow and weakly bound conduction electrons well separated from the K-shell binding energy. For a He target the maximum is found at 80 keV and for heavy targets between 70 and 150 keV. This dependence on the 1st binding energy and on the deeper level structure needs a detailed quantitative investigation and will not be further discussed here.

None of the above arguments explains the projectile-nuclear charge dependence. Hence, we have performed ab initio energy-loss calculations for a carbon target using the unitarized convolution approximation (UCA) [36,37] to uncover the physical origin of the $Z_p$ dependence. One example of theoretical results for Au + C is shown in Fig. 5 as a thick solid curve with open diamonds. As an input, we have used numerical oscillator strengths for each target shell. Furthermore, a charge-state distribution centered around the mean projectile-charge state defined by the above formulas was used including shell effects. We have additionally computed the electron-loss contribution to the stopping power using a single oscillator strength per projectile shell. Previously, we have shown that the uncertainty of such a procedure is <10% for heavy ions, even with less accurate charge-state formulas [46].

We find stopping-power maxima at 124 keV/u for He + C and at 2.8 MeV/u for Au + C (without $Z_p$ scaling). The corresponding SRIM values are 144 keV/u and 3.32 MeV/u, respectively. For He ions the SRIM values appear to be more reliable, since there exists a huge amount of data points for the fitting procedure [47] and on the other hand our ab initio code does not account for details of the valence-band structure. The situation is reverse for heavy ions. For the absolute values we find deviations of only about 7%, slightly outside the experimental errors, from the data by Geissel et al. [20] for Xe, Pb and U ions at 5 MeV/u. These heavy-ion data are underestimated in SRIM by 15–25%, with a maximum deviation for Pb. Thus, our UCA code yields accurate absolute values and at least a reasonable $Z_p$ dependence of the stopping maximum, when the target-shell structure, the projectile-charge distribution, projectile screening and the non-perturbative Bloch term are included in the calculation.

We have performed reference calculations also in first-order perturbation theory (without the Bloch term) and without consideration of the electron loss. The result is 160 keV/u, instead of 2.8 MeV/u when performing the full calculation. Consideration of electron loss would shift this perturbation-theory value further down in energy. Thus, the Bloch term is vital to the explanation of the energy scaling in Fig. 5. A full calculation for a fixed high projectile-charge state ($Au^{48+}$) shows the influence of the Bloch term very clearly. High energy losses are strongly suppressed in the corresponding results and there is a very broad stopping-power maximum centered around 670 keV/u. This, however, is still far below 2.8 MeV/u.

Thus, we need the Bloch term as well as the projectile-charge variation to explain the linear scaling in $Z_p$. For strong perturbations (slow heavy ions) the Bloch term leads to a strong suppression of

G. Schiwietz et al. / Nucl. Instr. and Meth. in Phys. Res. B xxx (2004) xxx–xxx

11

726 the ionization probabilities, specifically at small im-
727 pact parameters [48,36]. This flattens the stopping-
728 power curves below a few MeV/u and finally the
729 charge-state variation determines the resulting posi-
730 tion of the stopping-power maximum. An analysis
731 of Eqs. (2)–(5) suggests that the scaling factor
732 should be about $Z_p^{0.92}$ if the energy dependence of
733 the charge state alone would determine the stop-
734 ping-power maximum. The stopping-power maxi-
735 ma in Fig. 5 correspond to velocity-scaling
736 parameters around $x = 0.8$ or $\bar{q}^2 \approx 0.5 Z_p^2$ in Fig. 4,
737 where the projectile charges are steeply increasing.
738 In fact, we have also plotted the SRIM energy losses
739 versus $x$ from Eq. (2), but the scatter of the corre-
740 sponding stopping curves is comparable to the
741 one in Fig. 5. This scatter, however, is consistent
742 with the uncorrected target dependencies discussed
743 above.

744 **3. Electron spectroscopy**

745     The investigation of projectile quantities such as
746 scattering or energy loss may only yield information
747 on the prompt reaction of the solid. Delayed emit-
748 ted 'particles', however, may carry information on
749 the track evolution. Here we will concentrate only
750 on ejected electrons. Dependent on the material
751 and on the investigated emission process, electrons
752 are probes of the first $10^{-18}$–$10^{-14}$ s of track forma-
753 tion and energy dissipation. Examples of such snap-
754 shots of the electronic track evolution are given
755 below.
756     The experiments have been performed with
757 highly charged particles at velocities of 6–13% the
758 speed of light (at 1.78–8 MeV/u). In most cases the
759 ions were delivered by the heavy-ion cyclotron of
760 the Ionenstrahl-Labor (ISL) at the Hahn-Meitner-
761 Institut Berlin. The only exception are the 8 MeV/
762 u U$^{68+}$ data in Fig. 6 and one data point in Fig. 7
763 taken at the super-HILAC accelerator of the Berke-
764 ley National laboratory [49]. The Berlin setup is de-
765 scribed in detail in [50] and thus only a very brief
766 explanation shall be given here.
767     The heavy-ion beam of 100–500 nA is focussed to
768 a spot size of $2 \times 2$ mm at the target (normal inci-
769 dence) inside an ultra-high vacuum (UHV) cham-
770 ber. Inside this doubly magnetically shielded

Fig. 6. Experimental electron-energy distributions for 8 MeV/u U$^{68+}$ ions penetrating a thin amorphous carbon foil. The electron ejection-angle was varied between 0° and 180° with respect to the incident beam direction.

771 scattering chamber (reduction of the earth magnetic
772 field by a factor of 130) a high-resolution electro-
773 static electron spectrometer ($\Delta E/E = 0.1, \ldots, 1\%$)
774 rotatable around the target center is operated. A
775 stripper foil inside a doubly differential pumping
776 stage directly in front of the main chamber yields
777 a quasi-equilibrium charge-state distribution. This
778 method was applied for nearly all ions and, thus,
779 there is no influence of non-equilibrium charge
780 states and the corresponding reduction of track ef-
781 fects. In Figs. 7–9, however, we also present data
782 for the non-equilibrium charge-state ions
783 1.78 MeV/u Xe$^{15+}$ and 3.04 MeV/u Au$^{30+}$ in amor-
784 phous Si. In this case, we estimate that about 0.5
785 projectile electrons will be stripped off within the
786 first layer (corresponding to the mean free escape
787 depth [51] for the investigated Si-L Auger lines),
788 leading to a slightly enhanced mean projectile-
789 charge state. This enhancement is so small that it
790 has been neglected in the following.
791     Experimental results are presented for amor-
792 phous targets of graphite-like C (a-C, with an atom-

ic hydrogen fraction of <10%), Si (a-Si) and poly-propylene (PP, $C_3H_6$). Thus, we will be able to detect differences in the behavior of metals, semiconductors and insulators. The surfaces of the boron doped Si(1 1 1) samples ($\rho < 1\,\Omega\,cm$) were initially chemically etched and sputter cleaned with 2.5 keV Ar ions. Annealing at 850 °C was used to outgas the Ar contaminants, thereby recrystallizing the sample. Afterwards an amorphized surface layer down to a depths of about 14 nm was produced by irradiation with 5 keV Ar ions for a few minutes. All Si experiments have been performed under UHV conditions at residual gas pressures far below $10^{-9}$ mbar (dominated by $H_2$). The atomically clean target surfaces (all-over contaminations <3 at.%) were characterized by Auger-electron spectroscopy before and after the ion-irradiation cycles that were lasting a few hours, dependent on the actual vacuum conditions. In between, sputtering and amorphization with 5 keV Ar ions for up to 20 min was used to clean the samples.

All experiments with PP and most experiments with amorphous C (a-C) were performed with less sophisticated experimental setups [41,52] at residual pressures of $10^{-6}$ mbar, dominated by $H_2O$, without cleaning and annealing possibilities. a-C is quite inert to oxidation and furthermore, fast heavy-ion beams lead to an electronic desorption of surface contaminants. Thus, constant surface oxygen contaminations of typically a few atomic% were observed during the experiments. All results presented in this work are believed to be not affected by this coverage, since the coverage was stable after some minutes of heavy-ion irradiation. Moreover, the mean free electron-escape depth at an electron-emission angle of 135 °C corresponds to 4 layers in a-C (at an ejection energy of 270 eV) [51] reducing the relative influence of a surface coverage.

It is emphasized that Si is oxidizing rapidly under such vacuum conditions and at a typical energy of 90 eV the Auger signal is dominated by the upper two surface layers only [51]. Thus, for Si and for most other materials UHV conditions are absolutely necessary. Nevertheless, we have performed test experiments with slightly annealed diamond-like amorphous carbon (DLC), with sputter-cleaned graphite-like a-C as well as with cleaved and annealed crystalline graphite. Within the experimental uncertainty these UHV results for carbon agree perfectly with our previous data [53]. Thus, in this work we do not distinguish the UHV results for a-C from the majority of the data points.

Fig. 6 displays electron energy spectra for emission angles between 0° and 180° with respect to the ion-beam direction for 8 MeV/u U ions close to their equilibrium charge state in amorphous carbon. The measurements were performed with a low energy resolution of 7% to achieve high count rates at all energies. This plot shows the most important ejection mechanisms that can be investigated using electron spectroscopy.

There is a smooth continuously falling background visible at all angles. These electrons at energies between about 70 eV and several keV are the so-called δ-electrons. They are produced in violent binary collisions of the projectile ion with target electrons. At an ejection angle of 50° there is broad bump visible in the spectrum at an energy of about 7 keV. This bump corresponds to the electron energy

$$E_e^{binary} = \frac{4E_p m_e}{M_p}\cos^2(\theta_e) \qquad (6)$$

that reflects binary collisions between a heavy projectile and a free electron initially at rest. At larger angles this bump is too broad to be visible and at lower angles the binary-encounter energy exceeds the maximum experimental energy of 8 keV. Transport calculations show that the yield of fast electrons emitted in backward directions is due to the same binary-encounter processes followed by multiple angular scattering inside the solid [49]. At energies below about 70 eV there is a change of the spectral slope of the background due to the so-called soft-collision electrons or true secondary electrons. This structure belongs to a peak centered at an energy of a few eV and consists mainly of the slow electrons resulting from electron-collision cascades near the surface.

The most pronounced structure in Fig. 6 is found at 0° for a detection energy of 4400 eV. This is the convoy-electron peak and its electron-velocity vector corresponds to the projectile velocity. This peak is due to electron capture to the projectile continuum (ECC) and due to electron-loss to continuum

888 (ELC) processes. Its intensity is strongly influenced
889 by the long ranged Coulomb force of the projectile.
890 Convoy electrons suffer collisions with target elec-
891 trons and are steadily attracted by the projectile
892 Coulomb potential, giving rise to a random walk
893 in the projectile reference frame. The energy posi-
894 tion of the convoy peak is slightly sensitive to sur-
895 face potentials as well as to the ion-track potential
896 [55]. However, so far it was not possible to extract
897 quantitative track properties from such measure-
898 ments because of the complicated random-walk
899 processes. At angles between 20° and 40° one may
900 recognize weak bumps at an energy of about
901 4000 eV. These bumps are due to ELC processes
902 with somewhat larger energy transfers. Inside the
903 solid electrons are liberated from the projectile.
904 They start at about the projectile velocity and loose
905 a certain amount of energy until they reach the
906 surface.
907 At an electron energy around 270 eV, there are
908 peak structures superimposed on the continuous
909 δ-electron background in all of the spectra. These
910 peaks are the carbon KVV Auger structures (here
911 K stands for a K vacancy and each V stands for a
912 valence-band electron that is active during the Au-
913 ger decay). Auger peaks are due to the delayed
914 two-electron decay of inner-shell vacancies. In the
915 case of carbon a K vacancy is filled by a valence
916 electron and another valence electron is ejected.
917 The residual electron–electron interaction is respon-
918 sible for this transition and the Auger transition
919 rates for C-KVV and Si-LVV exceed the X-ray
920 transition rates by about a factor of 1000 [56]. From
921 such spectra measured at high resolution one may
922 determine the degree of inner shell ionization from
923 an analysis of the multiple peak structure (see Sec-
924 tion 4). Furthermore, it is possible to determine
925 the ion-track potential from an Auger peak-shift
926 (for a detailed discussion see Section 5) and the elec-
927 tron temperature in the valence band is related to
928 the high energy slope of the peak (see Section 6).
929 It is well known that fast electrons are predomi-
930 nantly ejected into forward directions (see also Fig.
931 6). This is a direct consequence of two-body colli-
932 sions dynamics. As has been shown in previous
933 investigations for carbon targets [41,49,54], these
934 fast electrons are so intense that the number of in-
935 ner-shell vacancies resulting from cascade collisions

936 inside the target is comparable to the direct inner-
937 shell ionization by the projectile ion. Thus, Auger
938 electrons that are emitted into the forward hemi-
939 sphere (from the ion-exit surface) in thin-film exper-
940 iments are to a large extend produced far away
941 from the track by secondary electron-collision cas-
942 cades. Contrary, Auger electrons ejected in back-
943 ward directions are mainly induced directly by the
944 projectile (in the central track region). Thus, in
945 the following detailed analysis of track effects only
946 data for a single fixed detection angle of 135° with
947 respect to the ion-beam direction are considered,
948 corresponding to 45° with respect to the surface
949 normal.
950 For all data presented subsequently, electron en-
951 ergy-spectra have been taken not only for incident
952 heavy ions. In addition reference and surface-con-
953 trol spectra where also taken with electrons at sim-
954 ilar incident velocities (1 and 2.7 keV at an incidence
955 angle of 45°). During the experiments, the electron
956 beam ($\varnothing < 1$ mm) is focussed at the centre of the
957 ion irradiated spot with an uncertainty of about
958 ±0.5 mm. Thus, surface coverages or ion induced
959 phase transformations may be detected in between
960 the ion runs.

## 4. Multiple ionization     961

962 In this section we present results on the intensity
963 of multiple inner-shell ionization of C and Si. A sin-
964 gle K vacancy in a-C leads to the peaks at about
965 270 eV in Fig. 6. Double K vacancies in a-C lead
966 to a broader shoulder around 310 eV (barely visible
967 in the figure because of low energy resolution and
968 low counting statistics in the double logarithmic
969 plot). Auger lines due to multiple inner-shell vacan-
970 cies decay in the same way as for a single vacancy.
971 These structures, however, are always shifted to
972 higher emission energies, since the reduced inner-
973 shell screening leads to an increased inner-shell
974 binding-energy. For the following discussion inten-
975 sity data are extracted from integrated multiple Au-
976 ger peak structures after subtraction of the δ-
977 electron background and an iterative separation of
978 the peaks belonging to different vacancy numbers.
979 It is emphasized that the vacancy production is
980 part of the energy-loss processes. The typical time

14                     *G. Schiwietz et al. / Nucl. Instr. and Meth. in Phys. Res. B xxx (2004) xxx–xxx*

981  for creation of a K vacancy is about $2 \times 10^{-18}$ s at
982  5 MeV/u. Thus, in comparison to all other impor-
983  tant time scales the Auger intensities are effectively
984  sensitive to the ion passage at time zero. They are
985  also only sensitive to the center of the infra track,
986  since the corresponding ionization probabilities
987  drop drastically beyond impact parameters of 0.5 Å.
988      As the carbon Auger spectrum has already been
989  introduced above, a short description of the Si Au-
990  ger spectrum is still needed for the discussions be-
991  low. The ion-induced target Auger spectrum of Si
992  involves Auger structures at energies between 88
993  and 132 eV due to one up to four L-shell vacancies
994  in the 2p shell ($2p^1VV$, $2p^2VV$, $2p^3VV$ and $2p^4VV$).
995  Furthermore, a vacancy in the 2s shell leads to fast
996  $2s2p^jV$ Koster–Kronig transitions (intrashell Auger
997  decay) at energies up to 42 eV, where one 2p elec-
998  tron (out of 6-$j$) fills the 2s-hole by transferring en-
999  ergy to a valence electron. In the following, line
1000 intensities for a-Si and a-C will be used to derive
1001 information on the initial degree of ionization in-
1002 side the track.
1003     Fig. 7 displays integrated Auger yields $Y_n$ for
1004 $n = 1$–4 inner-shell vacancies of a-Si and a-C [57].
1005 The sum of the data for each target is normalized
1006 to one. Results are plotted as function of the elec-
1007 tronic perturbation parameter or interaction
1008 strength $P = |q_{eff}|/v_p$, as it appears in quantum
1009 mechanical matrix elements for electronic excita-
1010 tions. The projectile velocity in units of the Bohr
1011 velocity ($2.19 \times 10^6$ m/s) is denoted as $v_p$, and the
1012 effective charge $q_{eff}$ is set equal to the mean incident
1013 particle charge state for projectiles in their charge-
1014 state equilibrium. Only for the non-equilibrium ions
1015 1.78 MeV/u $Xe^{15+}$ ($q_{eff} = 21$), 3.04 MeV/u $Au^{30+}$
1016 ($q_{eff} = 38$), and for 0.94 MeV/u $S^{6+}$ ($q_{eff} = 9$, dis-
1017 played in Fig. 7), we have modified $q_{eff}$ considering
1018 the projectile-electron loss at the surface and the re-
1019 duced projectile screening dependent on the in-
1020 volved projectile and target shell radii.
1021     Furthermore, we have reanalyzed the Si spectra
1022 for electrons, protons and $S^{6+}$ from the pioneering
1023 work by Schmidt et al. [58]. The results are shown
1024 as open symbols in the lower plot. It is noted that
1025 the spectra by Koyama et al. [59] have not been
1026 analyzed, since electron reference-spectra are miss-
1027 ing. High-energy data at 8 MeV/u by Caron et al.
1028 [60] for a-C targets are included as well in the plot

Fig. 7. Normalized experimental (symbols) and theoretical (lines) Auger yields as functions of the electronic interaction strength for incident electrons and heavy ions. The data in the upper plot are obtained for carbon and in the lower plot for silicon.

(open symbols). The error bars in Fig. 7 indicate       1029
all-over estimates of the uncertainty. In the figure    1030
we also have included theoretical results that are      1031
based on quantum mechanical ionization probabil-        1032
ities and classical transport theory as will be ex-     1033
plained in the following.                               1034
    For Si, the theoretical treatment is based on the   1035
Magnus approximation [34,53] (including shake-          1036
off) for ionization of the 2s0, 2p0 and 2p ± 1 states   1037
given by the Si Hartree–Fock–Slater potential. The      1038
resulting unitarized ionization probabilities for       1039
5 MeV/u have been calculated from total first-order     1040
Born ionization-probabilities $P_{B1}^{ion}(Z_p, b)$ according   1041
to                                                      1042

$$P_{M1}^{ion}(Z_p, b) = \sin^2\left(Z_p \sqrt{P_{B1}^{ion}(1, b)}\right) \qquad (7)$$

and converted into multiple-ionization cross-sec-       1045
tions using the (statistical) independent electron      1046
model (IEM). Auger cascades have also been con-         1047
sidered as explained further below. The 2pVV Au-        1048

1049 ger transition corresponds to a decay time of 15 fs,
1050 whereas the 2s2pV Koster–Kronig decay time is
1051 only 0.7 fs [56,61]. [1] Using simple statistics we esti-
1052 mate that the Koster–Kronig decay is faster than
1053 the $2p^nVV$ Auger transitions, even for a 4-fold ion-
1054 ized 2p shell ($n = 4$). Thus, 2s vacancies will lead to
1055 a 2s2pV transition, increasing the number of 2p
1056 holes from $n$ to $n + 1$. Afterwards, the $2p^nVV$ transi-
1057 tions will take place, leading to a remaining $(n - 1)$-
1058 fold ionized 2p shell. In this way, a whole series of
1059 Auger electrons results from one multiple-ioniza-
1060 tion event. At this point the theoretical results
1061 would represent a quasi-atomic case.

1062 Thus, corrections for the electron escape-depth
1063 and for δ-electron cascades inside the solid have
1064 been applied. Fast δ-electrons may produce single
1065 L-shell vacancies far away from the track. As we
1066 have estimated from our previous work for C tar-
1067 gets [52,54], considering the differences in backscat-
1068 tering yields and binding energies between C and Si,
1069 the total Auger-electron yield in Si contains a 30%
1070 fraction due to these δ-electron cascades and subse-
1071 quent $2p^1VV$ transitions.

1072 Furthermore, transport calculations of the en-
1073 ergy dependent electron escape-depths were per-
1074 formed including penetration of the surface
1075 barrier [62] with a focus on the high-energy behav-
1076 ior of the electron energy-loss spectrum for homo-
1077 geneously distributed electron sources at the
1078 experimental line positions. The emitted electron
1079 intensities have been integrated in the same way
1080 as for the experimental data. The resulting emission
1081 weight-factors are 0.50 (2s2pV), 1 ($2p^1VV$), 1.24
1082 ($2p^2VV$), 1.57 ($2p^3VV$) and 1.93 ($2p^4VV$) for the dif-
1083 ferent Auger lines. The final yield curves for $2p^nVV$
1084 are proportional to $P^{2n-2}$ for small values of the
1085 perturbation parameter $P$ (perturbation limit of
1086 the IEM) and for large values of $P$ they nearly reach
1087 a plateau. Exceptions are the curves for $2p^2VV$
1088 transitions, where an offset due to shake-off proc-
1089 esses is included, and for 2s2pV transitions which
1090 are both dominated by single ionization in the case
1091 of small $P$.

1092 Comparison of the experimental and theoretical
1093 results for $Si-2p^1VV$ and $Si-2p^2VV$ shows reasona-
1094 ble agreement. However, discrepancies become sig-
1095 nificant for the less intense lines and reach a factor
1096 of 0.27 for the $2p^4VV$ decay (note that we have ob-
1097 served an indication of 5-fold 2p ionization by Au
1098 projectiles). This reflects a well-known behavior of
1099 the IEM which neglects the dependence of the ion-
1100 ization potential on the degree of ionization. The
1101 flat behavior of the curves for high values of $P$ is re-
1102 lated to the Magnus prediction of an ionization
1103 probability close to 100% at small impact parame-
1104 ters. Accounting for the deviations between experi-
1105 ment and theory, there will be about *55% L-shell*
1106 *ionization and complete valence-band ionization* in-
1107 side a track diameter of about 1.6 Å for *U* projec-
1108 tiles at 5 MeV/u. For the a-C target the theoretical
1109 treatment is very similar and comparison with the
1110 experimental data shows a good overall agreement,
1111 especially for large perturbations. Thus, there is
1112 complete (6-fold) ionization of C for heavy ions
1113 with $Z_p > 30$ at 5 MeV/u.

1114 The above discussion shows, there is an enor-
1115 mous high degree of ionization directly after the
1116 interaction of the projectile with the target-electron
1117 system. The influence of this initial stage of the
1118 track evolution on the electron dynamics at much
1119 longer time scales is investigated in the next sec-
1120 tions. Specifically one may ask the question,
1121 whether the liberated electrons do return and screen
1122 the positive charges in the center of the ion track *be-*
1123 *fore* the Auger decay takes place.

## 5. Ion-track potential and Coulomb explosion 1124

1125 Strong ionization of atoms inside the ion track
1126 leads to a cylinder of positive charges and a result-
1127 ing positive ion-track potential. It is possible to de-
1128 tect this potential if the charge neutralization is slow
1129 enough. The ion-track potential does not act on
1130 emitted photons (no influence on X-ray line struc-
1131 tures), but it decelerates emitted electrons, which
1132 have to overcome the corresponding potential bar-
1133 rier. Line structures in the electron spectrum, either
1134 the convoy-electron peak or Auger lines, may be
1135 used to determine this deceleration. In fact, a decel-
1136 eration of convoy electrons compared to the projec-

---

[1] Seven measured values for the Si-2p lifetime deviate from each other and from [56] by up to a factor of 6. The value of 15 fs results from an average of the 5 most reliable results.

16                    *G. Schiwietz et al. / Nucl. Instr. and Meth. in Phys. Res. B xxx (2004) xxx–xxx*

tile speed (see the explanation of Fig. 6) as well as an Auger electron-deceleration has been found for the insulators polypropylene (PP, $C_3H_6$) and also Mylar [52,55,63]. In the following, Auger results for PP will be compared to recent data for a-Si [50,57].

Similar to the previous section the Auger line-shift is sensitive to the potential in the center of the track, since the residual electron–electron interaction is short ranged. Contrary to the previous section, however, the line-shift is determined by the solid-state environment during the statistically delayed Auger decay process. Typical Auger decay times are 11 fs ($11 \times 10^{-15}$ s) for carbon $K^1VV$ and 15 fs for silicon $2p^1VV$ lines. For multiple vacancy lines ($C$-$K^2VV$ and also Si-$2p^2VV$, Si-$2p^3VV$,...) the decay times are significantly reduced. Hence, an analysis of the Auger line positions for different vacancy states yields snapshots of the potential evolution inside the track for different times.

Fig. 8 displays Auger energy reductions, determined relative to a reference value, as a function of the perturbation parameter $P = |q|/v_p$. Note that $q$ has been used here instead of $q_{eff}$ as in Fig. 7, since inner-shell excitations are of minor importance for the track potential, and valence-band excitations are dominated by the projectile–electron interactions at large impact parameters. Peak positions corresponding to fast electron- or proton-induced spectra serve as a zero reference-value for the Si values in this plot. This choice shall be explained in detail before the results of Fig. 8 are discussed. For the insulator PP the situation is much more complicated, since there is a strong macroscopic charging during electron irradiation, which vanishes nearly completely during heavy-ion irradiation. Therefore, other materials namely amorphous carbon and $[C_{2.1}H_{0.6}]_n$ instead of $[C_3H_6]_n$ had to be used for the energy reference. Both reference materials show no significant Auger shift. For details of this method the reader is referred to [52,53,63].

For light charged-particle induced ionization as well as for non-resonant X-ray induced photo ionization of inner shells, there are only minor dependencies of the line shape or position on the primary excitation. Auger lines as well as X-ray emission lines show the so-called dynamic initial-state screening effects. Typically, these are weak secondary

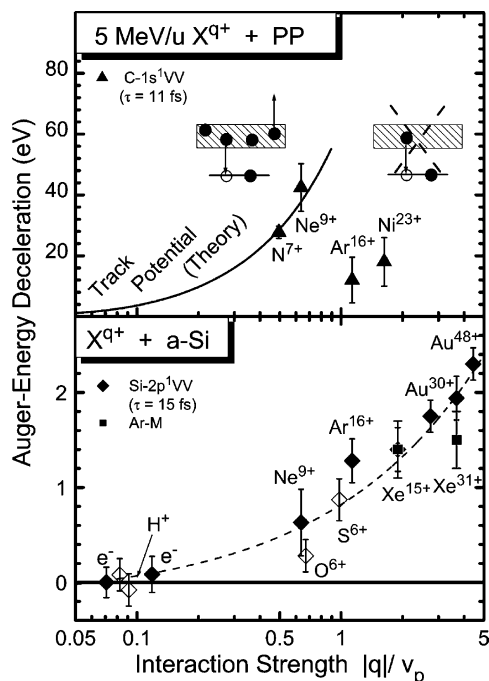

Fig. 8. Auger energy reduction versus $|q|/v_p$. The upper plot shows the carbon KVV Auger-energy shift obtained for polypropylene (PP) samples in comparison to track theory. The lower plot shows LVV energy shifts for amorphous Si.

modifications of the initial-state population triggered by the dynamics of the ionization process. Quite often shake-up and shake-off processes determine the dynamic initial-state screening for weakly interacting particles such as individual photons or electrons. As an example, one may notice that the relative $2p^2VV$ ionization yield in Fig. 1 approaches a finite value of 0.8% for fast incident electrons and protons (shake-off limit at $P \ll 0.1$) and reaches 20% for swift heavy ions at 5 MeV/u (dominated by second-order two-step mechanisms).

In Fig. 8, data are presented for the carbon $1s^1VV$ Auger peak of polypropylene [52,53,63] and for two Auger peaks corresponding to the Si target. The $2p^1VV$ peak corresponds to the main line of Si (see Fig. 7) and the Ar-M peak corresponds to a weak Ar contamination after sputter cleaning that has been detected in two of the experiments. The open symbols for a-Si have been extracted from the spectra by Schmidt et al. [58] for

17

1205 electrons, $H^+$, $O^{6+}$ and $S^{6+}$. The dashed curve for Si
1206 is shown to guide the eye.

1207    As mentioned above δ-electron induced vacan-
1208 cies at the ion-entrance surface constitute a fraction
1209 of only about 7% for a thick a-C target. They may,
1210 however, amount to 30% for the a-Si target because
1211 of enhanced backscattering yields for higher values
1212 of $Z_t$. It is noted that we have not performed a cor-
1213 rection for the influence of δ-electron cascades on
1214 the silicon $2p^1VV$ line position. This awaits a more
1215 detailed understanding of the line shape.

1216    The carbon peak-shifts increase with the interac-
1217 tion strength $P$ up to a value of about 42 eV at
1218 $P = 0.6$. For larger interaction strengths the ion-
1219 track potential seems to drop to a much lower va-
1220 lue. The initial rise of the potential is consistent with
1221 the solid curve, a computed ion-track potential [52].
1222 The model is a combination of classical-trajectory
1223 Monte Carlo calculations for the electron motion
1224 in the field of the projectile ion under the assump-
1225 tion of a continuous-slowing down behavior inside
1226 the solid. Thus, the electron displacements are com-
1227 puted as a function of time and the sum over all
1228 positive and negative Coulomb potentials yields a
1229 screened track potential dependent on the time
1230 and on the distance to the center of the track.

1231    The good agreement between experimental data
1232 for N and Ne ions and the model results is taken
1233 as evidence for a strong suppression of track neu-
1234 tralization. The values for Ar and Ni ions, however,
1235 are much lower. This is also consistent with the
1236 model as for $P > 0.8$ there are less than two valence
1237 electrons per atom in the center of the track. Thus,
1238 Auger decay is impossible and the Auger clock
1239 stops (this is also indicated by the crossed out tran-
1240 sition scheme in Fig. 8). Only at a later stage during
1241 the slow neutralization process there will be two va-
1242 lence electrons or more, which is the necessary con-
1243 dition for the Auger transition. Consequently, for
1244 very heavy ions the Auger decay takes place in an
1245 electronically relaxed environment and the resulting
1246 Auger shift must be far below the value of the initial
1247 track potential.

1248    Thus, all PP results in Fig. 8 appear to be com-
1249 pletely consistent with a long-lived strong ion-track
1250 potential. Quantitative estimates indicate that the
1251 track life-time is $>1.5 \times 10^{-14}$ s. Thus, for heavy
1252 ions, the ion-track potential in polypropylene is

1253 strong enough and survives long enough to allow
1254 at least for a partial Coulomb explosion of the pro-
1255 tons in the polymer. Indications for a strong erosion
1256 due to Coulomb explosion [53] and for a related
1257 small energy shift of ejected hydrogen ions [64] have
1258 been found. For other carbon structures, such as
1259 amorphous diamond-like and graphite-like carbon
1260 as well as crystalline graphite, energy shifts are be-
1261 low the corresponding experimental uncertainty of
1262 2 eV. Thus, neutralization is much faster in these
1263 materials and Coulomb explosion cannot take
1264 place.

1265    The silicon peak-shifts in Fig. 8 increase mono-
1266 tonically with the interaction strength $P$ and reach
1267 about 2.3 eV at $P = 4.4$. Furthermore, the shifts
1268 are very similar for the different Si Auger lines
1269 (see [57] for preliminary evaluations of other Si
1270 lines). Macroscopic charging of the B-doped Si
1271 samples can be excluded for the observed effect,
1272 since no indication of a peak shift could be found
1273 for incident electrons at different beam currents.
1274 Material modifications can be excluded as well,
1275 since the electron reference-spectra, taken before
1276 and after the ion-measurement cycles, are identical
1277 to within an uncertainty of ±0.15 eV.

1278    Thus, we also attribute the measured shift for Si
1279 to the ion-track potential induced by a local reduc-
1280 tion of the electron density as a result of ionization
1281 in the center of the track. Auger electrons are decel-
1282 erated when leaving such a positively charged re-
1283 gion. From our previous investigations of this
1284 effect for polypropylene (PP, see upper part of
1285 Fig. 8) and Mylar [52,53,63], we estimate that the
1286 initial track potential directly after the interaction
1287 with the projectile should be about 250 V for
1288 $Xe^{31+}$ ions (at $|q|/v_p = 3.7$) and nearly independent
1289 of the material. Thus, the measured shift of only
1290 2.3 eV in silicon is strongly influenced by the time
1291 dependent electronic neutralization of the track.
1292 Assuming an exponential decay, however, a time
1293 dependence of the potential should show up in the
1294 different Si Auger line-shifts that cover effective de-
1295 cay times from about 1 to 17 fs. Hence, the major
1296 part of the neutralization is very rapid (<1 fs) and
1297 the measured shift seems to be related to a very slow
1298 and weak component of the ion-track potential that
1299 might be due to long-lived traps (trapped excitons

1300 and populated defect states) in the amorphous
1301 material.
1302     Significant ion-track potentials seem to be exclu-
1303 sively related to either insulators or semiconductors.
1304 No significant line shifts have been found for metals
1305 so far. Correspondingly, a Coulomb explosion can
1306 be excluded for metals as well as for a-Si (because
1307 of the small value of the track potential). Thus,
1308 material modification processes in metals call for a
1309 different energy conversion mechanism as will be
1310 discussed in the following section.

1311 **6. Electron temperatures, thermal spike and lattice**
1312 **relaxation**

1313     In this section we will analyze implications of the
1314 thermal spike and lattice relaxation models as a re-
1315 sult of highly excited track cores after neutraliza-
1316 tion. Experimental data for the electron
1317 temperature after neutralization, the main ingredi-
1318 ent of both models, are presented for the first time
1319 for a-Si. Similar as in Section 5, the temperature
1320 data are sensitive to the center of the track and to
1321 the Auger decay times of a few femtoseconds.
1322     So far, we have investigated the intensity (see
1323 Fig. 7) and the shift of Auger lines (see Fig. 8).
1324 But the slope of the Auger lines carries information
1325 about the degree of excitation of the valence band
1326 during the vacancy decay. The high energy shoulder
1327 of the Auger structures reflects a convolution of the
1328 populated density of states near the Fermi level
1329 [65,68,69]. As described in detail in previous publi-
1330 cations on a-C [66] the line widths increase with
1331 increasing projectile-charge state related to an
1332 increasing electron temperature. The data evalua-
1333 tion is based on a comparison with Auger spectra
1334 for incident electrons, as a reference for the electron
1335 transport properties. First we fit these spectra using
1336 a simple model for electron transport [67] that in-
1337 cludes the density of states, assuming that the corre-
1338 sponding electron temperature in the valence band
1339 is nearly zero. Electron temperatures are then ex-
1340 tracted from fits to ion induced spectra, by variation
1341 of the Fermi–Dirac distribution and by keeping all
1342 other transport properties fixed.
1343     Fig. 9 displays experimental electron tempera-
1344 tures versus interaction strengths $P = |q|/v_\mathrm{p}$ for the

Fig. 9. Electron temperature as determined from the broadening of the dominant Auger line of amorphous Si for different projectiles at 1.8–5 MeV/u. The dashed curve is shown to guide the eye.

Si-$2p^1$VV-Auger decay. The error bars indicate the 1345
overall uncertainty of the current evaluation domi- 1346
nated by the curve-fitting procedure. The measured 1347
temperature is monotonically and slowly increasing 1348
with $P$ and reaches about 15,000 K for 3 MeV/u 1349
Au$^{48+}$ ions. It is emphasized, however, that these 1350
data should be taken as preliminary since δ-electron 1351
cascades have not been considered in the evalua- 1352
tion. The δ-electron cascades are expected to reduce 1353
the broadening of the measured Auger lines, since 1354
they contribute 'cold' secondary Auger electrons 1355
from regions that are far away from the track. Cor- 1356
respondingly, we expect that the analyzed tempera- 1357
tures will rise by about 30% when this effect is 1358
included. 1359
    Furthermore, it is possible to improve the accu- 1360
racy of the fit significantly when improved partial 1361
density of states (PDOS) are considered. An analy- 1362
sis of the PDOS [68,69] used in this work in com- 1363
parison to experimental data for UV and X-ray 1364
photo-electron emission (UPS and XPS), high reso- 1365

19

lution soft X-ray emission spectroscopy (XES), X-ray absorption near-edge spectroscopy (XANES) and bremsstrahlung isochromate spectroscopy (BIS or inverse XPS) has clearly revealed inconsistencies between experiment and theory. Thus, a more involved analysis of the PDOS for Si is necessary and more recent accurate theoretical results [70] should be used as a guideline to determine a more reliable PDOS from the experimental data.

Previous data for graphite-like amorphous carbon [66] and other carbon modifications [53] did not show such problems, since the corresponding PDOS [65] is broad due to the extremely high Fermi energy of a-C and graphite. The results for C show a similar tendency as a function of P as the ones displayed in Fig. 9. However, for high projectile energy-losses electron temperatures of about 80,000 K are reached. These have been compared with two thermal-spike models. Comparison with results of the free-electron code by Toulemonde and coworkers [12] show up to an order of magnitude deviation for light ions. This failure of simple thermal-spike models and the corresponding data from two experimental groups are presented and discussed in a review article by Rothard within this topical issue. It should be noted, however, that improved theoretical treatments accounting for the DOS of a-C in the computation of the electronic heat capacity and the electronic thermal conductivity agree to within 35% with the experimental data.

Accounting for the influence of δ-electron cascades in Si, electron temperatures will probably exceed 20,000 K. This might be high enough to trigger phase transitions in Si if the electron–phonon coupling is strong. At these high temperatures, however, about 12% of the valence electrons are excited into higher lying surface states and continuum states of the bulk. Under such conditions a spontaneous lattice-relaxation, driven by interatomic non-equilibrium potentials, can also not be excluded as a material modifications mechanism [8].

## 7. Conclusions

The energy dissipation due to fast heavy ions in matter is investigated with special attention on track effects at the very center of an ion path on a sub-picosecond time scale. Basic energy-transfer mechanisms and electronic relaxation processes are reviewed in the light of recent experimental and theoretical developments.

From the view point of a swift heavy projectile, its speed and its charge state and the resulting energy transfer to the target are the most important parameters that determine track-production processes. Ion charge-states in matter can now be predicted with high precision on the basis of a semiempirical fit to the existing data. Projectile-shell effects, a target dependence of the mean charge-state and now also resonance effects have been identified with high significance. Especially for surface experiments, but also for thin-film experiments, non-equilibrium charge-states have to be considered if the mean energy loss shall be a meaningful parameter for the analysis of experimental data [37].

It is shown that the energy loss of fast ions is reasonably well understood. A non-trivial explanation for the approximate $Z_p$ scaling of the energy at the stopping-power maximum has been found in this work. The deviations between experimental stopping powers and theoretical ab initio results are currently below 10% for fast heavy ions. It even seems that current ab initio stopping powers [36–40] are more accurate for fast heavy ions than the most recent version of the well-known semiempirical SRIM tabulations [45]. Consistent inclusion of the accurate mean charge states presented here, of electronic polarization effects (the so-called Barkas term) [38,71] and of excited projectile states [39,72–75] is expected to reduce the theoretical uncertainties by another factor of 3, an important goal for precision ion-beam analysis. Finally one would be limited by dynamic mean-field effects and electron-correlation effects which are difficult to include in a many-electron treatment. Already today, however, the prediction of impact-parameter dependent non-equilibrium or equilibrium energy-losses appears to be no significant source of uncertainty for the explanation of track effects (at $E_p/M_p \gg 100$ keV/u).

Reasonable agreement is also found in a comparison of experimental and theoretical probabilities for multiple inner-shell ionization. For very heavy ions these results indicate that the center of the track is extremely strong ionized. For light targets such as carbon this even means *complete ionization*

*of all target electrons.* Thus, after the ion passage the electronic structure inside a track is far away from equilibrium. The track volume is transformed into a highly charged column with hot electrons surrounding the ion path.

Hence, the main unsolved question concerning material modifications by fast ions is 'how are such strong electronic excitations converted into atomic motion?' In order to get some first answers to this question, high resolution in situ electron-spectroscopy is applied to swift heavy-ion–solid interactions. Note that the possibilities of high resolution target X-ray spectroscopy have not even been partially explored until today.

In this work, we have presented and discussed results of target electron-spectroscopy for the three materials amorphous graphite-like carbon (a-C), polypropylene (PP, $[C_3H_6]_n$), and amorphous silicon (a-Si). Some published results exist also on crystalline graphite (HOPG) and amorphous diamond-like carbon (DLC) [53], on Mylar [63] as well as preliminary data on Si(1 1 1) with a 7×7 reconstruction [57]. On the basis of work in progress, we also do have further information on thin oxygen-implanted insulator films of $Al_2O_3$ and BeO [76] as well as on the pure metals Be and Al and a few metallic glasses [77].

The behavior of all these materials may be characterized in terms of two electronic properties that determine the atomic evolution of ion tracks

• *Ion-track potential.* For the insulators polypropylene and Mylar we have found high ion-track potentials and extremely high electronic sputtering yields with a threshold behavior. Both facts are strong indications for the Coulomb explosion mechanism, a mutual repulsion of highly ionized atoms. For the a-Si semiconductor a small positive potential is found, but it is definitely too weak to lead to a Coulomb explosion. For the insulating thin oxide films, however, there seems to be no significant ion-track potential according to a preliminary analysis. To within uncertainties of ±0.3 eV to ±1 eV, all other investigated materials also do not show indications for an ion-track potential. Coulomb explosion can definitely be ruled out for these solids. Thus, some defect rich insulators or semiconductors with non-polar bonds seem to favor track potentials, but details remain unclear at the moment.

• *Electron temperature.* For the all materials where electron reference spectra could be obtained we found a broadening of the ion induced Auger spectra. This broadening is related to high electron temperatures in a range of about 15,000–85,000 K for projectile ions with $Z_p > 50$ at a few MeV/u. These electron temperatures may lead to material modifications via the electron–phonon coupling (thermal-spike model) or via the modified interatomic forces (lattice-relaxation model). A first analysis of the possible dependencies points to an influence of the electronic density of states (DOS) on the electron temperature. Large quasi-gaps at the Fermi level such as in a-C, HOPG and Be seem to yield the highest electron temperatures.

In summary, the Auger decay of multiple inner-shell vacancies yields snapshots of the track evolution for times between 1 and 20 fs. A significant ion-track potential seems to persist for some femtoseconds only in case of a few solids. High electron temperatures, however, seem to be a very general phenomenon. It is still an open question, whether material modifications are triggered by the electron–phonon coupling (thermal spike) or by the lattice relaxation (cold melting). So far, it has not been possible to distinguish between the two energy-conversion mechanisms on a pure experimental basis. From the present work, however, it becomes clear that the pathways for material modifications by fast heavy ions (Coulomb explosion versus thermal spike) are strongly dependent on the type of material.
